

This is an RE slide set, with many slides created by DVJ.

RE stands for "Residential Ethernet", and 802.1 study group.

Alternative names abound, which mean the same thing: Residential Bridges, Residential Bridging AV Bridges, Audio/Visual Bridges, etc.

Credit is due to many others, whose reviews/comments evolved this concept.

The clock-distribution scheme is that of IEEE 1588.

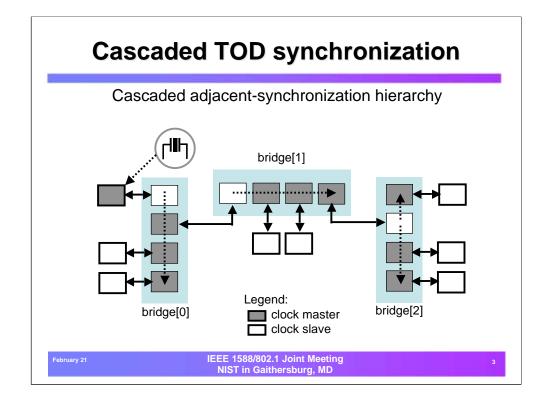

The grand clock master (grand master) is the station whose time-of-day clock is the reference.

From a logical perspective, the clock master broadcasts the current time-of-day to the attached stations.

From a physical perspective, such a multicast time distribution would be inaccurate:

- 1) There may be source transmission delays.
- 2) There may be bridge forwarding delays.

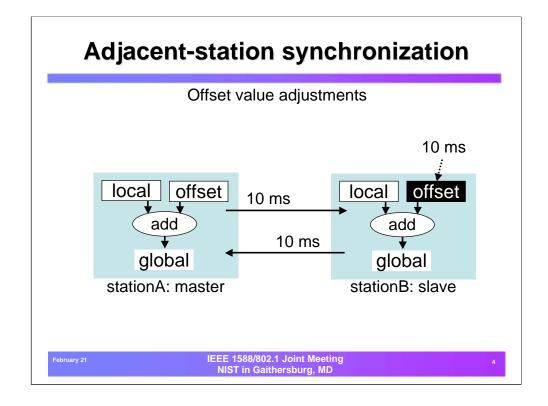

Therefore, a more-precise synchronization protocols is used.

To avoid propagation-time inaccuracies:

Synchronization is done on a point-to-point basis Internal bridge distribution (port-to-port) is "magical" and beyond our scope.

A key point: its no enough to standardize how one identifies slave errors: One must address how the slave eliminates errors. One must address how cascaded slaves compensate cumulative errors.

Initial studies indicate a faster update rate is practical.

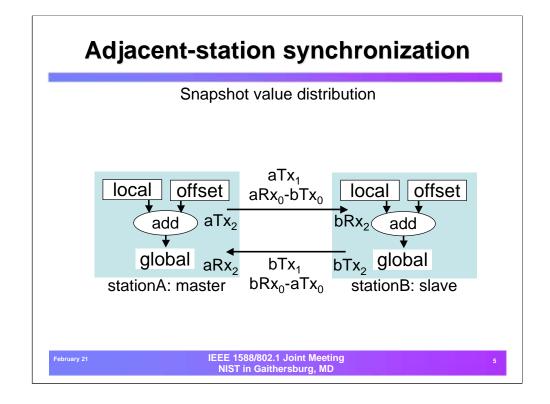

While 1ms is practical, a slower 10ms allows the cheapest of microprocessors.

The primary purposes of these transfers are for:

Grand-master selection (reduces rogue frame stabilization times)

Offset adjustments, to force current time acceptance

(For precise synchronization, rate adjustments may also be required.)

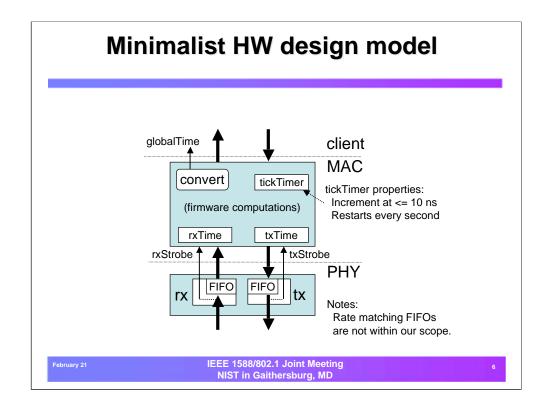

Time snapshots are best sent in the next "cycle".

Cheap: easily implemented in hardware (and possibly firmware).

Precise: observations are more precise than predictions

In the case of stationB, the aTx and aRx values must be sent, since these were measured by stationA and are not known to stationB.

The value of bTx is (in concept) known to stationB and need not be transmitted. However, for simplicity, transmission of this value allows it to be more easily affiliated with the same-cycle indexed aRx value.

What is the hardware design model?

Simple hardware to snapshot the arrival/departure times

The local time reference (a minimum frequency is sufficient) is OK.

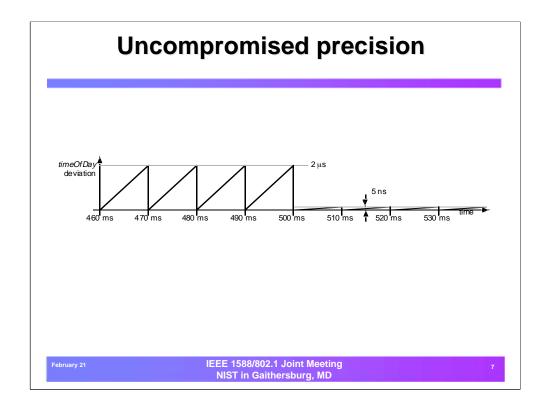

External communications are through normalized time values.

Firmware performs the conversions, frame formatting, etc.

Several strategies for precise snapshots are possible:

FIFOs add ambiguity (existing hardware)

The MAC arranges for FIFOs to be nearly empty, at critical times The PHY signals the actual clockSync arrival/departure times

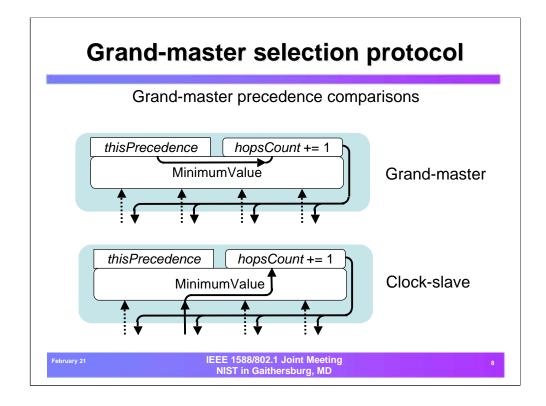

With a 200PPM clock deviation, offset adjustments have limitations.

The problem is the drifts, due to clock-frequency differences.

Thus, the most apparent solution is to have the "slave" match the rate of the master.

Frequency deviations are easily measured, from time snapshots measured over a larger time interval (100ms, perhaps).

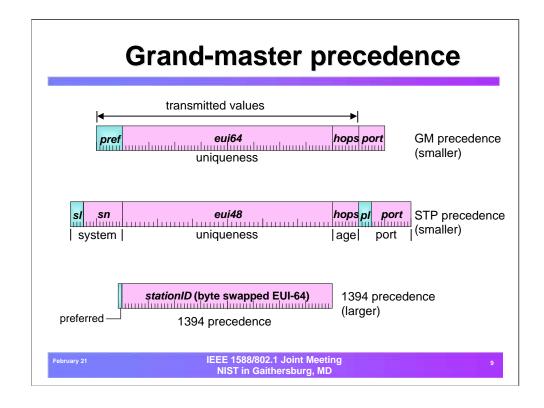

Various frequency compensation schemes are possible; the above waveform illustrates one possible scheme.

For the grand-master selection, spanning-tree protocol is popular in 802.1.

The "minimum" value is distributed throughout the network.

A hopCount value breaks ties, in favor of the shortest-span lengths.

What is the precedence value?

The precedence numbers must be unique, so that only one clock master will be selected. For this purpose, the station address is sufficient.

To communicate preferences, a *pref* (station priority) value is provided. This overrides the MAC address, allowing users to assert their preferences. This weighting can be accessed through the MIB.

For stations with equal *pref* values, the *eui64* becomes the tie breaker. This resolves grand-master in a unique (but somewhat arbitrary) manner.

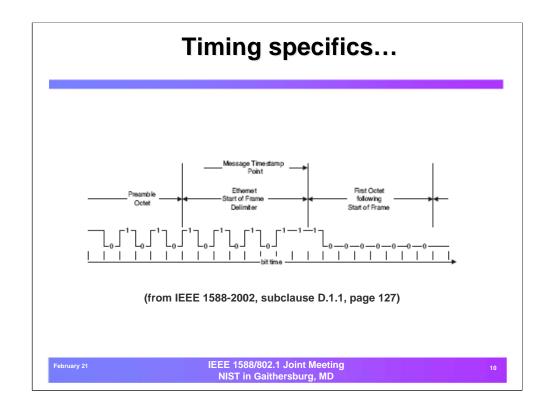

For ports on a station, the *hops* value selects port with the shortest distance from the grand-master, measured in hops-through-bridges. In the case of a tie, the port number selects the preferred path.

The lowest numerical value has the highest precedence.

Default weighting of *pref* is the mid-range numerical value.

The setting of other weights is a higher level protocols and is beyond the scope of this standard.

The 802.1 spanning-tree protocol assumes "smart" things set the precedence, "simple" things do the comparisons. This is similar, but simpler while remaining compatible with 1394 and networks with 64-bit MAC addresses.

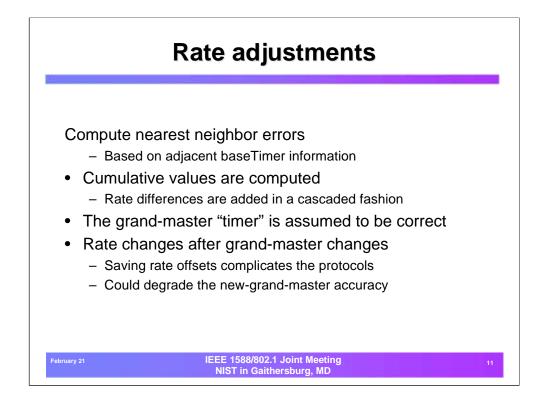

What (exactly) is the frame arrival/departure time?

Depends on the physical layer details.

Some are already specified, in IEEE 1588.

Parallel-bit transmission schemes may need clarifications.

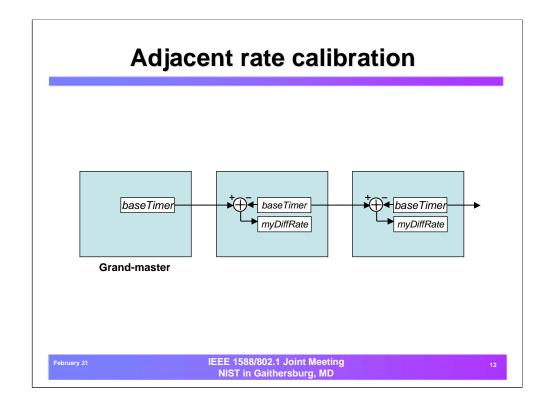

- 1G CAT-5
- 10G (in general?)

Rate synchronization involves:

100 ms to track temperature differences longer than 10ms to reducing sampling inaccuracies

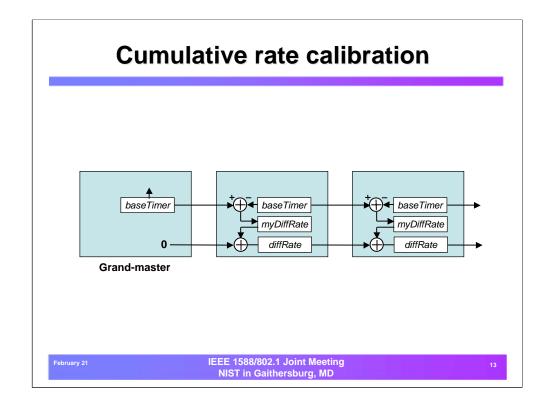

In general, timers are never reset or changed scaling values can be multipliers offsets values can be additions

Adjacent station offset computations involve periodic time forwarding.

The *baseTimer* value is a fixed-rate timer, with identical nominal rates. In reality, may be any convenient HW timer, with firmware conversions.

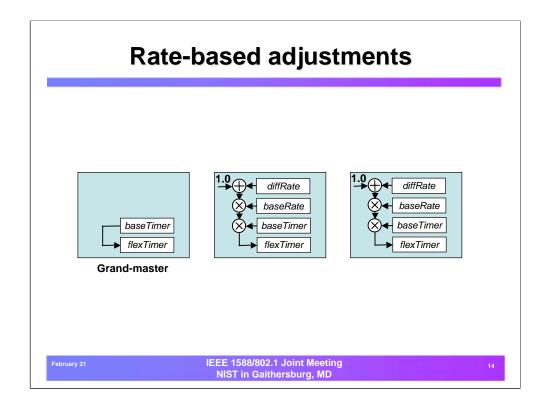

Based on neighbor interchanges, the neighbor drifts are computed.

The adjacent-neighbor drifts are accumulated downstream.

Thereafter, each station's *diffRate* value accurately represents the drift from the grand-master, rather than one's adjacent neighbor.

While oftentimes illustrated separately, both are done concurrently: Compute the next value of *myDriftRate* Accumulate the cumulative *driftRate* values

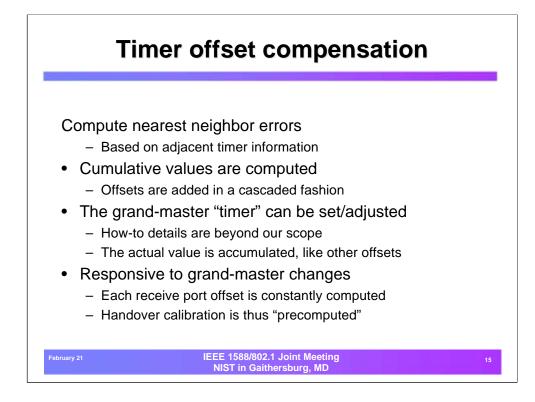

The accumulated rate differences are applied to flexTimers.

In the grand-master, they are both the same (although actually in error).

For the other clock-slave stations, the flexTimer runs possibly faster or slower.

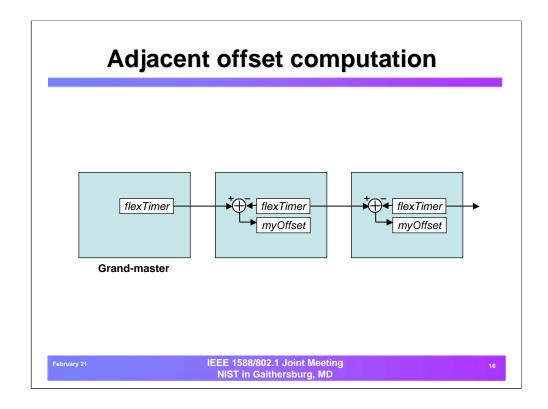

The implementation of these multipliers is conceptual only and only computed on demand (not every clock tick).

Timer synchronization involves:

offset-time adjustments, 10 ms for short-term coarse-grained tracking offset-rate adjustments, 100 ms for long-term fine-grained tracking

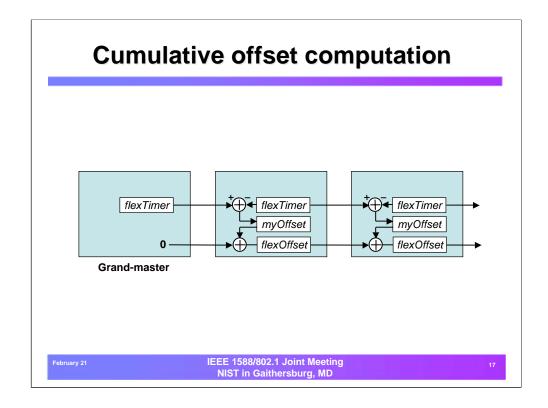

Again, timers are never reset or changed offset values are added, these can be changed

Adjacent station offset computations involve periodic duplex exchanges.

Based on neighbor interchanges, the neighbor differences are computed.

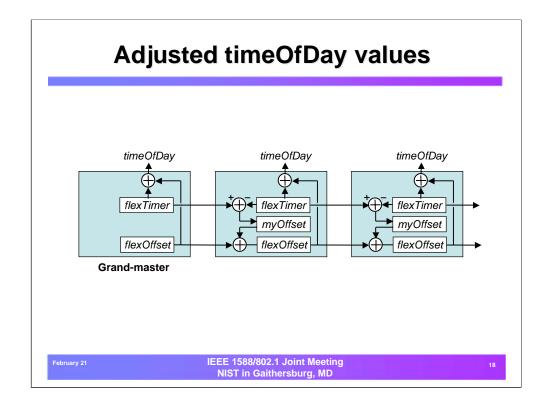

The *flexTimer* value is adjusted-rate timer, with identical nominal rates. In reality, there will be minor inaccuracies. Nearly insignificant, due to the longer sampling times.

The adjacent-neighbor offsets are accumulated downstream.

Thereafter, each station's *flexOffset* value accurately represents the offset from the grand-master, rather than one's adjacent neighbor.

While oftentimes illustrated separately, both are done concurrently: Compute the next value of *myOffset* Accumulate the cumulative *flexOffset* values

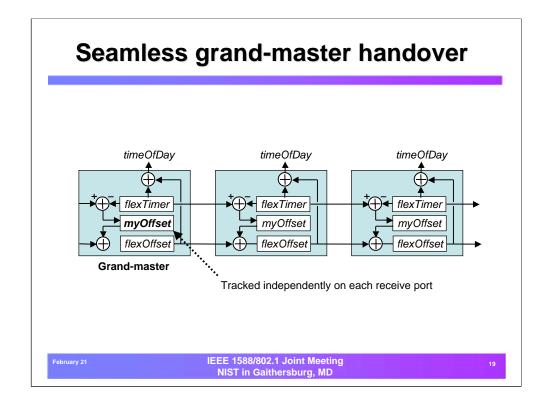

Cumulative offset values allow the slaves to track the grand-master.

However, the grand-master's time may be set incorrectly.

Changing the grand-master's *flexTimer* would have bad consequences, causing potentially large discontinuities in *myOffset* values.

Instead, a distinct *flexOffset* value is distributed.

While the time discontinuity is unavoidable, the computed myOffset values are undisturbed by the transient.

What if the grand-master changes?

This could by:

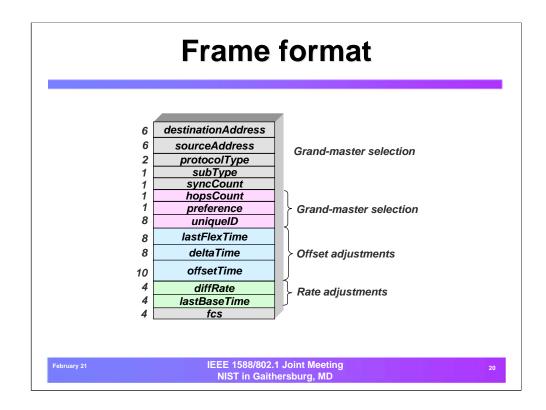

another station being added a grand-master preference being changed

Or, the path from the grand-master could be changed.

To reduce such transient effects, the grand-master monitors receive ports. Its receive port independently/constantly computes *myOffset* values.

When a handover occurs, the nearly correct *myOffset* value is available, so *flexOffset* discontinuities are minimal.

This assumes the new grand-master maintained synchronization by: Participating (as a clock-slave station) in synchronization protocols. Maintaining synchronization through other means (e.g., radio station). Maintaining precise time through physical design (e.g., atomic clock).

What is contained within each frame?

The standard header.

A syncCount to detect missing frames, thus avoiding last-cycle sampling errors.

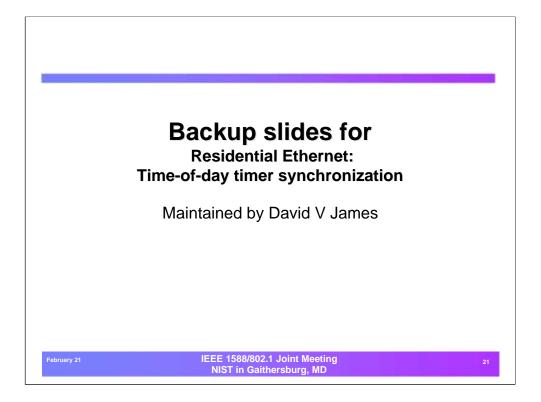

Values for the grand-master selection.

Values for the offset adjustments

Values for the rate adjustments

And, this all fits in a minimum-length 64-byte frame!

(Thus, there is no advantage to having "smaller" frames.)

Backup slides, for pre-review and-or extended question responses.

The main consideration is to be cheap:

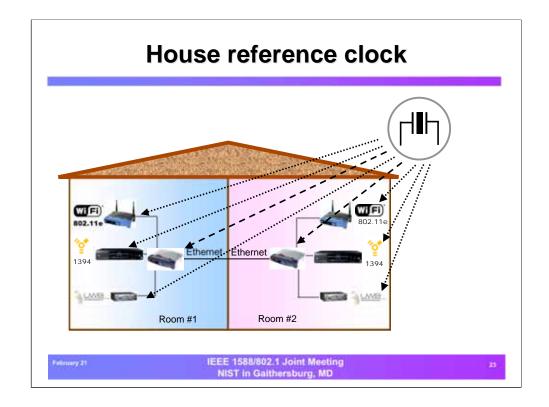

Easily integrated into consumer bridges. Easily integrated into consumer end-points.

Simplicity is valued, since fewer mistakes are likely to be made. Delayed snapshots avoid time-critical processing requirements Symmetric processing reduces process-sequence steps

Precision is valued, since audio-files are very sensitive ps jitter desired, although theoretical and filtered is probably OK Minimal-glitch handovers due to accurate/symmetric compensations

Robustness is also critical, with minimal-glitch handovers.

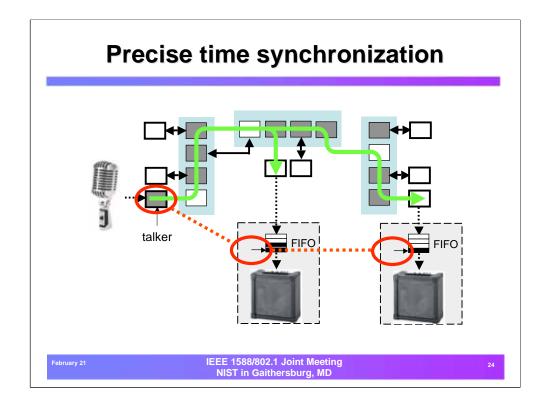

Is this realistic? Fortunately, we can benefit from existing IEEE 1588 knowledge. without its legacy constraints (e.g., broadcast CSMA/CD).

In support of synchronous transfers, all RE devices are assumed to have the same impression of time.

For this presentation, assume an 8kHz cycle time, although a decision on this value has not been finalized.

Requirement: 8kHz cycle frequencies are locked and the "same

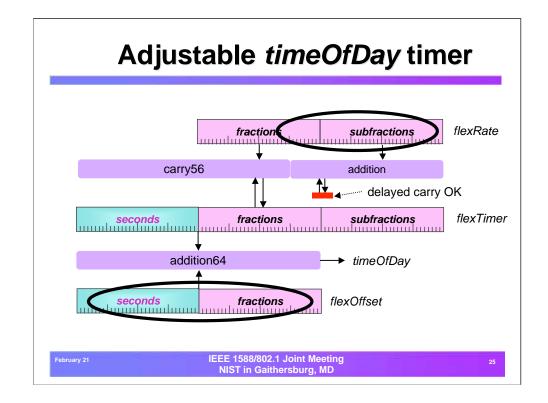

Data arrives early; data is gated at its presentation time.

(Each frame has a presentation time stamp.)

Bridge reclocking has a relatively modest clock-sync accuracy requirement, where microsecond deviations could be acceptable.

Source-data and presentation-data clocking requirements are more severe.

- 1) Frequency drift is unacceptable, since dropped/replicated values are audible.
- 2) Presentation time jitter is sub nanosecond, based on slew rates and D/A accuracies.

The basic model assumes rate-adjustable and offset-adjustable clocks. Since bridge values are rarely needed:

Any high-enough frequency clock is sufficient Value can be converted "on-demand".

The rate can be adjusted, by updates to flexRate.

The offset can be adjusted, by changes to flexOffset.

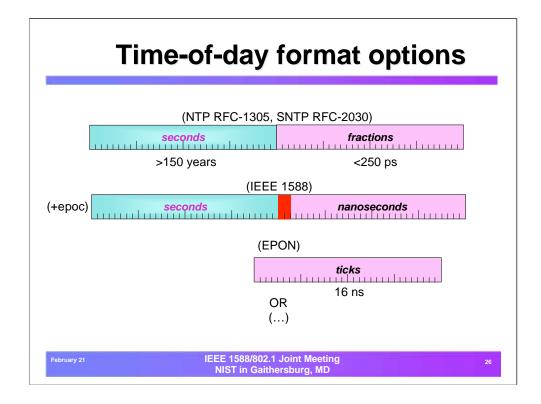

How is a fractions-of-second timer conceptually implemented? Clocks are typically multiples of something else!

The clock can tick at a natural rate, and the tick-size need-not be "one".

For example, consider a clock that is updated with a 16ns clock. The update value is 68.719476736

Since the LSB is insignificant, the carry can be delayed

The less significant bits provide precise rate adjustment, for precise tracking

What is synchronized?

Preferably a binary seconds and fractions-of-seconds value.

Doesn't overflow within our lifetimes.

Time resolution induced errors are insignificant.

Easily added and subtracted.

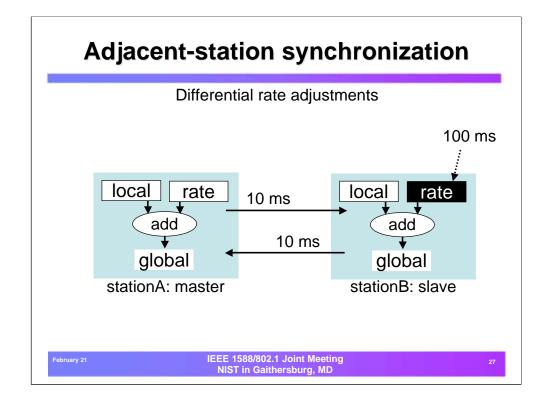

Readily converted to other formats...

Other formats are also possible:

because we have 10 fingers

a multiple of the cycle frequency

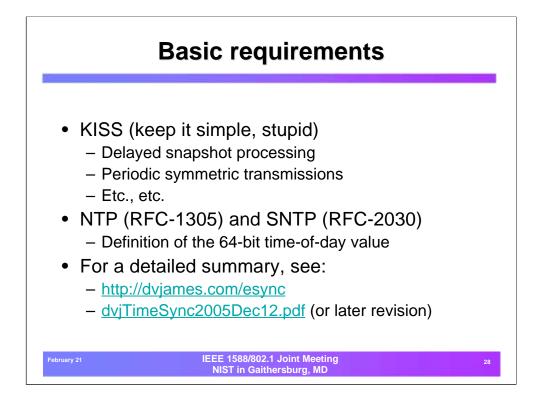

....

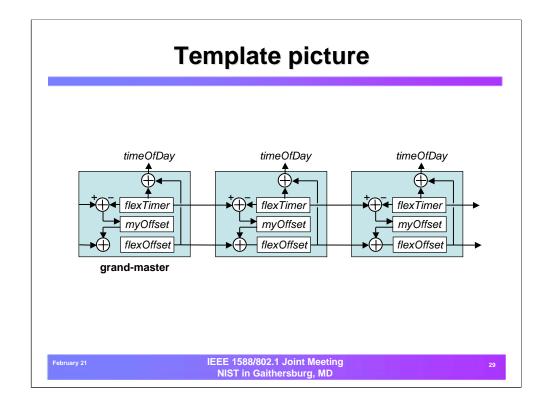

Adjacent-station synchronization is preferrably done less frequently, so that the time-snapshot errors are smaller.

For a 10x longer interval, the effective frequency error is nearly zero.

Yet, the sampling interval is small enough to compensate for modest timevarying temperature drifts.

What is the hardware design model?

Simple hardware to snapshot the arrival/departure times

The local time reference (a minimum frequency is sufficient) is OK.

External communications are through normalized time values.

Firmware performs the conversions, frame formatting, etc.

Several strategies for precise snapshots are possible:

FIFOs add ambiguity (existing hardware)

The MAC arranges for FIFOs to be nearly empty, at critical times The PHY signals the actual clockSync arrival/departure times
